(57) **ABSTRACT**

An information processing apparatus includes an interface unit, a detection unit, an unmount unit, a display unit, and a control unit. The interface unit connects a reader/writer device, which is capable of receiving a memory storage medium. The detection unit detects a connection and a disconnection between the interface unit and the reader/writer device. The unmount unit sets the memory storage medium to an unmounted state. The a display unit display information about a detection result by the detection unit. The control unit controls, in response to the detection unit detecting that the reader/writer device is temporary disconnected from the interface unit, the display unit not to display information about the temporary disconnection of the reader/writer device from the interface unit.

FIG. 9

# INFORMATION PROCESSING APPARATUS, AND METHOD FOR CONTROLLING THE SAME

## CROSS REFERENCE TO RELATED APPLICATIONS

The present application is a continuation of U.S. patent application Ser. No. 12/818,933, filed on Jun. 18, 2010, which claims priority from Japanese Patent Application No. 2009-149802, filed Jun. 24, 2009, all of which are hereby incorporated by reference herein in their entirety.

## BACKGROUND OF THE INVENTION

### 1. Field of the Invention

The present invention relates to an information processing apparatus that is connectable to an external device (peripheral device) via an interface.

### 2. Related Background Art

Conventionally, a Universal Serial Bus (USB) interface has been used to establish a connection between a host apparatus and an external device. When a host apparatus is connected to an external device, the host apparatus detects the connection of the external device to a USB interface, through a device driver for example, and performs a process to make the external device accessible. When the host apparatus receives an instruction to disconnect the external device from an operator, the host apparatus performs processing for shifting a state that the external device can be disconnected therefrom. If the external device is physically disconnected from the host apparatus, the host apparatus detects the disconnection of the external device from the USB interface using a device driver for example, and performs processing for shifting a state that the external device is disconnected therefrom.

In such a system, sometimes an unintended event, for example static electricity is applied to the external device, may accidentally happen and make the electrical connection between the host apparatus and the external device temporarily disconnected. In such a case, a turn-off and restart of the host computer is necessary and a recovery may take long time. To address this problem, Japanese Patent Application Laid-Open No. 2003-131956 discusses a technique in which a circuit of a general interface for transmission and reception of data between a host apparatus and an external device is restarted. Japanese Patent Application Laid-Open No. 2008-27379 discusses a technique for restarting a device control module in a host apparatus.

In the conventional techniques, when an information processing apparatus such as a host apparatus is electrically disconnected temporarily from an external device due to static electricity for example, a device control module is restarted to reset the external device to a connection state. Such approach to recover the connection, however, does not store the previous connection state of the external device before the disconnection. Thus, even when the device control module is restarted to connect the host apparatus to the external device again, the restored connection state is not always the same state before the disconnection. In this case, when the host apparatus attempts to access the external device based on the connection state before disconnection, the host apparatus may not be able to access the external device due to a mismatch between the connection states before and after the disconnection.

## SUMMARY OF THE INVENTION

The present invention relates to an information processing apparatus, when an external device connected to the informa-

tion processing apparatus via an interface is temporarily disconnected, and then reconnected, that can access the external device based on a connection state before the disconnection.

According to an aspect of the present invention, an information processing apparatus includes an interface unit configured to connect a reader/writer device which is capable of receiving a memory storage medium, a detection unit configured to detect a connection and a disconnection between the interface unit and the reader/writer device, an unmount unit configured to set the memory storage medium to an unmounted state, a display unit configured to display information about a detection result by the detection unit, and a control unit configured to control, in response to the detection unit detecting that the reader/writer device is temporary disconnected from the interface unit, the display unit not to display information about the temporary disconnection of the reader/writer device from the interface unit.

According to an exemplary embodiment of the present invention, even if an accidental disconnection, which is not intended by an operator, of a device from an information processing apparatus happens, the operator can use the device without being conscious of the disconnection and reconnection of the device. Accordingly, operability of the information processing apparatus can be improved.

Further features of the present invention will become apparent from the following description of exemplary embodiments (with reference to the attached drawings).

## BRIEF DESCRIPTION OF THE DRAWINGS

The accompanying drawings, which are incorporated in and constitute a part of the specification, illustrate exemplary embodiments, features, and aspects of the invention and, together with the description, serve to explain the principles of the invention.

FIG. 1 is a block diagram illustrating an example configuration of a digital multifunction peripheral.

FIG. 2 is a block diagram illustrating example of system software configuration of a digital multifunction peripheral.

FIG. 3 is a flowchart illustrating processing for detecting a USB device in a digital multifunction peripheral.

FIG. 4 illustrates an example of connection state information.

FIG. 5 is a flowchart illustrating processing for disconnecting a USB device in a digital multifunction peripheral.

FIG. 6 illustrates examples of detected information.

FIG. 7 illustrates examples of management information.

FIG. 8 is a flowchart illustrating processing for connecting a USB device in a digital multifunction peripheral.

FIG. 9 is a flowchart illustrating processing for updating management information in a digital multifunction peripheral.

## DESCRIPTION OF THE EMBODIMENTS

Various exemplary embodiments, features, and aspects of the invention will be described in detail below with reference to the drawings.

FIG. 1 is a block diagram illustrating an example configuration of a digital multifunction peripheral that is an example of an information processing apparatus. A digital multifunction peripheral 100 includes a controller unit 101 in which a central processing unit (CPU) 102 controls the entire system of the digital multifunction peripheral 100. A random access memory (RAM) 103 is a system work memory for operations of the CPU 102. A read only memory (ROM) 104 is a boot

ROM storing system boot programs. A hard disk drive (HDD) **105** stores system software and the like.

An operation unit interface (I/F) **106** is an interface unit to an operation unit **107**, and outputs information to the operation unit **107** for display thereon. The operation unit I/F **106** transmits information input via the operation unit **107** by an operator to the CPU **102**. The operation unit **107** includes a display unit including a liquid crystal display and an operation unit including a touch panel sheet, hard keys and the like.

A USB host interface (I/F) **108** serves as an interface to a USB device such as a memory card reader/writer **109**. In the present exemplary embodiment, a USB device such as the memory card reader/writer **109** is used for description as an example of an external device or a peripheral device, but the external device may include a USB memory and other devices. The USB host I/F **108** outputs information input from the operation unit **107** or information stored in the HDD **105** to the memory card reader/writer **109**. The USB host I/F **108** also transmits information obtained from the memory card reader/writer **109** to the CPU **102**. The units **102** to **108** are connected to a system bus **110**. The USB host I/F **108** is connected to the memory card reader/writer **109** using a USB cable. The USB host I/F **108** may be provided with a plurality of USB connectors. In this case, among the plurality of USB connectors, a specific USB connector is managed to be connected to the memory card reader/writer **109**.

The system bus **110** is also connected to an engine interface **111**. The engine interface **111** is further connected to a scanner engine **112** and a printer engine **113**.

In the present exemplary embodiment, the memory card reader/writer **109** is an example of a USB device. Other examples of the USB devices include a USB memory, a USB hard disk (HDD), a digital camera, an audio player, a cell phone, a compact disk (CD)/digital versatile disk (DVD) drive, and an integrated circuit (IC) card reader. The memory card reader/writer **109** of the present exemplary embodiment is provided with a plurality of slots that allow insertions and connections of different types of memory cards **114** which are compact storage media. The memory card reader/writer **109** also enables connections of a plurality of the memory cards **114** simultaneously. Examples of the memory cards **114** include a secure digital (SD) card, a Smartmedia, a CompactFlash (registered trademark), a memory stick, a microdrive, and the like, and the memory card reader/writer **109** reads and writes data from and in these devices.

Alternatively, the memory card reader/writer **109** may be provided with a USB hub, so that another USB device can be connected to the memory card reader/writer **109**.

FIG. 2 is a block diagram illustrating a configuration of system software of the digital multifunction peripheral according to the present exemplary embodiment. Each of components **200** to **205** in FIG. 2 is a program module that is stored in the ROM **104** or the HDD **105** in FIG. 1 to be executed by the CPU **102**.

An application unit **200** provides a user interface to an operator for reference to the memory card **114**, and reading and writing of data from and to the memory card **114** via the operation unit **107**. The application unit **200** receives operation input information from the operator, and also gives an instruction to the control unit **201** to obtain a state of the memory card **114**. Alternatively, the application unit **200** receives information that indicates a connection (mount) state of the memory card **114** from the control unit **201**. In this case, the control unit **201** accepts the instruction to obtain the state of the memory card **114** from the application unit **200**, and

notifies the application unit **200** of the connection state of the memory card **114** connected to the memory card reader/writer **109**.

The control unit **201** includes a state notification unit **202**, a state management unit **203**, and a state detection unit **204**. The state notification unit **202** receives the information that indicates the connection state of the memory card **114** connected to the memory card reader/writer **109** from the state management unit **203** and the state detection unit **204**, and notifies the application unit **200** of the received information. The state management unit **203** manages the connection state of the memory card **114** connected to the memory card reader/writer **109**, the states being detected by the state detection unit **204**. The state detection unit **204** inquires about a current connection state of the memory card reader/writer **109** to the operating system **205**, and obtains and manages information indicating the connection state as a detection result.

The state detection unit **204** detects a connection and/or a disconnection of the memory card reader/writer **109** based on the information obtained from the operating system **205**. Then, the state detection unit **204** detects whether the memory card **114** is connected to the memory card reader/writer **109**, and notifies the state notification unit **202** and the state management unit **203** of a detection result.

When the memory card **114** is connected to the memory card reader/writer **109** by the system software processing, the state detection unit **204** detects the connection of the memory card **114**, and the state management unit **203** stores the connection information of the memory card **114** in the RAM **103**. The connection information is notified to the application unit **200** via the state notification unit **202**. Accordingly, the information of the memory card **114** can be output (displayed) onto the operation unit **107** which makes the memory card **114** accessible. When the memory card **114** is brought to a usage interruption (unmounted) state, the state detection unit **204** detects the disconnection of the memory card **114**, and the state management unit **203** deletes the connection information of the memory card **114** from the RAM **103**. Then, the disconnection information is notified to the application unit **200** via the state notification unit **202**. Accordingly, the disconnection information of the memory card **114** is output (displayed) onto the operation unit **107**, and the displayed information of the memory card **114** is deleted. Thus, no more operation to access the memory card **114**, which is already removed, can be performed by the operator.

Upon a reception of an instruction to disconnect the memory card **114** from the operator, the state detection unit **204** performs processing for unmounting the memory card **114**. In response to the processing result, the state management unit **203** deletes the connection information of the memory card **114** from the RAM **103**. Unmount information is notified to the application unit **200** via the state notification unit **202**. Consequently, information indicating that the memory card **114** is processed to be disconnected is output to the operation unit **107**, and simultaneously the information of the memory card **114** that has been displayed on operation unit **107** is deleted, to make the memory card **114** inaccessible by the operator.

The present exemplary embodiment is described on assumption that the memory card reader/writer **109** is connected to the digital multifunction peripheral **100** in a housing. In other words, in the present exemplary embodiment, the digital multifunction peripheral **100** is not physically disconnected from the memory card reader/writer **109** in normal use. Sometimes, however, for example when a user touches the memory card reader/writer **109**, static electricity may be generated which results in noise in electrical signals between

5

the USB host I/F **108** and the memory card reader/writer **109**. The noise brings the electrical connection between the USB host I/F **108** and the memory card reader/writer **109** into an abnormal state temporarily, and the operating system **205** cannot recognize the memory card reader/writer **109**. This phenomenon is equivalent to that the physical connection between the USB host I/F **108** and the memory card reader/writer **109** is momentarily disconnected and then reconnected. Thus, the state detection unit **204** detects a temporary disconnection of the memory card reader/writer **109**. The control unit **201** also detects a usage interruption (unmount) of the memory card connected to the memory card reader/writer **109**.

A method for recovering a previous connection state before disconnection when a temporary unmount of the memory card reader/writer, which does not occur under normal circumstances, accidentally happens will be described. By the method, the memory card reader/writer is made accessible using the previous connection information before disconnection on the operation unit **107**, even when the reconnection of the memory card reader/writer is provided as new connection information to the operating system **205**. The detail will be described below.

FIG. 3 is a flowchart illustrating processing for detecting a USB device in the digital multifunction peripheral **100**. The processing illustrated in the flowchart is executed by the CPU **102**.

First, a USB device such as the memory card reader/writer **109** is connected to the USB host I/F **108**. Upon recognition of the physical connection of the USB device, the operating system **205** reads a necessary driver from the HDD **105**, and obtains device information from the USB device to store in the RAM **103** as connection state information. The operating system **205** assigns an access point to the USB device as a device file. The device file is one example of device specifying information that is generated by the operating system **205** to specify the USB device.

FIG. 4 illustrates an example of connection state information. A device filename **401** includes names of the above described device files. When the USB device is the memory card reader/writer **109** that has a plurality of slots, a device file is assigned to each of the slots. Accordingly, the operating system **205** can specify the slot based on the device file name, and then specify a memory card inserted in the slot. A vendor identification (VendorID) **402** includes a vendor ID for each USB device, and a ProductID **403** includes a product ID for each USB device. A serial number **404** can be used for identifying a specific unit of the USB device. A state **405** indicates a connection state of the device, and includes information such as "connected" and "disconnected" (or identifiers for each of the states). FIG. 4 illustrates the case where a memory card reader/writer having three slots is connected, and each of the slots is assigned with a device file. In the case where a memory card reader/writer having a different number of slots is connected to the USB host I/F **108**, the number of device files is assigned to the slots respectively.

The processing illustrated in flowchart in FIG. 3 is started under the conditions as described above. In step S301, the state detection unit **204** obtains the connection state information of the USB device from the operating system **205**. In step S302, the control unit **201** analyzes the obtained connection state information of the USB device and determines whether the USB device is connected. If the control unit **201** determines that the USB device is connected (YES in step S302), the processing proceeds to step S303. In step S303, connection processing of the USB device is performed (which will be described below) and then the processing ends. On the

6

other hand, if the control unit **201** determines that the USB device is not connected (NO in step S302), the processing proceeds to step S304. In step S304, disconnection processing of the USB device is performed (which will be described below) and the processing ends.

FIG. 5 is a flowchart illustrating processing for disconnecting a USB device in the digital multifunction peripheral **100**. The flowchart illustrates details of the processing in step S304 in the flowchart in FIG. 3.

It is assumed that the digital multifunction peripheral **100** according to the present exemplary embodiment can use only a specific memory card reader/writer. Accordingly, a VendorID and a ProductID for the specific memory card reader/writer are stored in a specific area (specific device information storage area) in the HDD **105** as specific external device information (specific peripheral device information). There may be a plurality of VendorIDs and ProductIDs stored in the HDD **105** as specific external device information.

In step S501, the state detection unit **204** compares the VendorID and the ProductID that are managed as the specific external device information with a VendorID and a ProductID in the connection state information obtained from the RAM **103** for analysis. In step S502, the state detection unit **204** determines whether the disconnected USB device is the memory card reader/writer specified by the specific external device information, and if the USB device is not the specific memory card reader/writer **109** (NO in step S502), the processing ends. Whereas if the USB device is the specific memory card reader/writer **109** (YES in step S502), the processing proceeds to step S503. In step S503, the state detection unit **204** updates the detected information stored in the RAM **103** which is managed by the state detection unit **204**, based on the information of the disconnected memory card reader/writer **109**. The detected information will be described below.

FIG. 6 illustrates examples of the detected information in the state detection unit **204**. The detected information includes several items. A device file name **601** is information assigned by the operating system **205** to specify a slot of the memory card reader/writer **109** and is equivalent to the device file name **401** in the connection state information in FIG. 4. A VendorID **602** includes an ID of a vendor of the memory card mounted (i.e., in an available state) to a slot. A ProductID **603** includes a product ID of the memory card mounted to a slot. A serial number **604** can be used for specifying an individual memory card mounted to a slot. Identification information **605** is a unique ID for identifying a memory card and is issued by the state detection unit **204** when the memory card is successfully mounted. In the identification information **605** of the present exemplary embodiment, a drive letter represented by one alphabet is used as an example, but any information that identifies a memory card may be used. A state **606** indicates a connection state of a memory card which is represented by either MOUNTED (the memory card is inserted and connected to the slot) or UNMOUNTED (the memory card is removed from the slot and disconnected). A previous device file name **607** includes the last device file name before disconnection which is stored when the memory card reader/writer **109** is disconnected.

The detected information **600A** illustrates information example when the memory card reader/writer **109** is connected. The detected information **600B** illustrates information example when the memory card reader/writer **109** is disconnected. The detected information **600B** includes, in the previous device file name **607**, the device file name of each slot before the memory card reader/writer **109** is disconnected.

7

The detected information **600C** illustrates information example when the disconnected memory card reader writer **109** is reconnected. The detected information **600C** includes, in the previous device file name **607**, the device file name of each slot before the memory card reader writer **109** is disconnected. At this point, in the device file name **601** in the detected information **600C**, a device file name is described which is newly assigned by the operating system **205** to each slot for the reconnection. It will be noted that the device file name **601** and the previous device file name **607** for the same slot are different from each other.

In step **S503** of the flowchart in FIG. **5** illustrating processing for disconnection of the USB device, the detected information is updated from the detected information **600A** to the detected information **600B**.

Then, in step **S504**, it is determined whether there is a mounted memory card in the memory card reader writer **109**. More specifically, the determination is performed by searching for management information of the memory card from the management information managed by the state management unit **203**. The management information will be described below.

FIG. **7** illustrates examples of the management information managed by the state management unit **203**. The management information of the memory card connected and mounted to the memory card reader writer is managed in the form of a table, and the information about each memory card is stored in the RAM. **103** as one record. The management information includes a device file name **701**, VendorID **702**, ProductID **703**, serial number **704**, identification information **705**, and temporary-disconnection flag **706**. The device file name **701**, the VendorID **702**, the ProductID **703**, the serial number **704**, and the identification information **705**, include the same information as the information in the device file name **601**, the VendorID **602**, the ProductID **603**, the serial number **604**, and the identification information **605** in FIG. **6**, respectively. The temporary-disconnection flag **706** is a flag for indicating a state of usage interruption (i.e., unmount) of the memory card due to disconnection between the USB host I/F **108** and the memory card reader writer **109**. "ON" in the temporary-disconnection flag **706** corresponds to unmount of the memory card.

The management information **700A** illustrates information when two memory cards are mounted. The management information **700B** illustrates information when the USB host I/F **108** is disconnected from the memory card reader writer **109**. The management information **700C** illustrates information when the USB host I/F **108** is reconnected to the memory card reader writer **109**. Processing for updating the management information will be described below.

In step **S504**, if there is no record in the management information, or no memory card is connected (NO in step **S504**), the processing ends. On the other hand, if there is a record in the management information, or at least one memory card is connected (YES in step **S504**), the processing proceeds to step **S505**.

In step **S505**, a temporary-disconnection state is recorded in the corresponding record of the memory card in the management information managed by the state management unit **203**. In other words, the records in the temporary-disconnection flag **706** in the management information **700A** are changed to "ON" for updating the information as illustrated in the management information **700B**. In step **S506**, processing for unmounting the memory card in the slot is performed, and the processing ends. At this point of time, no notification of the disconnection is made from the state notification unit **202** to the application unit **200**. It is because the disconnection

8

between the USB host I/F **108** and the memory card reader writer **109**, which does not occur under normal circumstances, can be considered to be caused by static electricity which is expected to be recovered in a short time. Therefore, since the disconnection of the memory card due to a reason the operator does not know is not displayed on the operation unit **107** according to the above processing, unnecessary confusion of the operator can be avoided.

FIG. **8** is a flowchart illustrating processing for connecting the USB device in the control unit **201**. The flowchart illustrates details of the processing in step **S303** in the flowchart in FIG. **3**.

Upon recognition of the physical connection of the USB device, the operating system **205** obtains device information from the USB device to store the information in the RAM **103** as connection state information. The operating system **205** assigns an access point to the USB device as a device file.

In step **S801**, the state detection unit **204** analyzes information about the VendorID and the ProductID based on the connection state information obtained from the RAM **103**. In step **S802**, the state detection unit **204** determines whether the connected USB device is the specific memory card reader writer **109** based on the analysis result, and if the device is not the specific memory card reader writer **109** (NO in step **S802**), the processing ends. If the state detection unit **204** determines that the memory card is the specific memory card reader writer **109** (YES in step **S802**), the processing proceeds to step **S803**.

In step **S803**, it is determined whether the information is the same as that of the memory card reader writer **109** which is stored at the time of disconnection. More specifically, it is determined whether the VendorID and the ProductID in the updated detected information **600B** in step **S503** match the VendorID and the ProductID of the connected memory card reader writer **109**. If the information is not the same as that of the memory card reader writer **109** which is stored at the time of disconnection (NO in step **S803**), the processing ends. If the information is the same as that of the memory card reader writer **109** which is stored at the time of disconnection (YES in step **S803**), the processing proceeds to step **S804**.

In step **S804**, it is determined whether the memory card is connected to the connected memory card reader writer **109**. The determination can be made by accessing the device file using the device file name managed in the detected information **600B**. If no memory card is connected (NO in step **S804**), the processing ends. If the memory card is connected (YES in step **S804**), then in step **S805**, it is determined whether the memory card is already mounted.

If the memory card is mounted (YES in step **S805**), the processing ends. If the memory card is not mounted (NO in step **S805**), then in step **S806**, processing for mounting the memory card is performed. In step **S807**, processing for updating the management information is performed. The step **S807** will be described in detail below.

Then in step **S808**, the previous device file name is deleted from the detected information, and the processing ends. At this point of time, no notification of the connection is made from the state notification unit **202** to the application unit **200**.

In this way, when a temporary disconnection and reconnection happened due to an unknown reason to the operator, the reconnection can be achieved without making the operator aware of this, and an access can be made to the same operation memory card as that before the disconnection.

FIG. **9** is a flowchart illustrating processing for updating the management information in the control unit **201** performed by the CPU **102**. The flowchart illustrates details of the processing in step **S807** of the flowchart in FIG. **8**.

In step S901, the state management unit 203 obtains a first record of the management information (i.e., the information 700B in FIG. 7). In step S902, the state management unit 203 determines whether the temporary-disconnection flag is ON. If the temporary-disconnection flag is ON (YES in step S902), the processing proceeds to step S903.

In step S903, it is determined whether the device file name of the record in the management information 700B matches the previous device file name in the management information 600B which is updated in step S503 in FIG. 5. If the device file names match with each other (YES in step S903), the processing proceeds to step S904.

In step S904, the device file name of the record in the management information 700B is changed to the device file name in the detected information. In other words, at the reconnection, the operating system 205 updates the device file name to a device file name newly assigned to the memory card slot. Then, the temporary-disconnection flag for the record is updated from ON to OFF. Accordingly, the management information 700B is updated to the management information 700C.

On the other hand, if the temporary-disconnection flag is not ON (NO in step S902) or the device file names do not match with each other (NO in step S903), the processing proceeds to step S905. In step S905, it is determined whether there is a next record in the management information. If there exists a next record in the management information (YES in step S905), then in step S906, the state management unit 203 obtains the next record, and the processing returns to step S902. If there is not a next record (NO in step S905), the processing ends.

As a result of the processing of the flowchart in FIG. 9, identification information (e.g., drive letter) in the management information is displayed on the operation unit 107 as access information. Even if static electricity is applied, the identification information (e.g., drive letter) of the memory card displayed on the operation unit 107 is not changed. Since the state management unit 203 updates the device file associated with the identification information that is specified by the operator to the device file that is changed after the reconnection, access to the reconnected memory card can be established. Consequently, even if the USB host I/F 108 is temporarily disconnected from the memory card reader/writer 109 due to applying of static electricity for example, an operator can access the memory card by the same operation as that before the disconnection.

In the present exemplary embodiment, a case is described where the memory card reader/writer 109 is disconnected while an operator is not accessing a memory card. However, even when the memory card reader/writer 109 is disconnected while the user is accessing the memory card (e.g., reading or writing data from or to the memory), the processing for reconnection can be performed similarly. In this case, however, since an access operation being performed is interrupted, a notification of the failed operation may be made only when the disconnection happens during the access, and an instruction for re-reading and/or rewriting data from and to the memory may be output to the operation unit 107.

According to the above described exemplary embodiment, even when the memory card reader/writer is temporarily disconnected due to applying of static electricity for example, access to the memory can be made without making an operator aware of the disconnection which is not intended by the operator.

Aspects of the present invention can also be realized by a computer of a system or apparatus (or devices such as a CPU or MPU) that reads out and executes a program recorded on a

memory device to perform the functions of the above-described embodiment(s), and by a method, the steps of which are performed by a computer of a system or apparatus by, for example, reading out and executing a program recorded on a memory device to perform the functions of the above-described embodiment(s). For this purpose, the program is provided to the computer for example via a network or from a recording medium of various types serving as the memory device (e.g., computer-readable medium).

While the present invention has been described with reference to exemplary embodiments, it is to be understood that the invention is not limited to the disclosed exemplary embodiments. The scope of the following claims is to be accorded the broadest interpretation so as to encompass all modifications, equivalent structures, and functions.

What is claimed is:

1. An information processing apparatus comprising:
  - an interface unit configured to connect a reader/writer device into which a memory card can be inserted and from which the memory card can be detached;
  - a detection unit configured to detect, as detection result, a connection and then a disconnection between the interface unit and the reader/writer device, and a reconnection of the reader/writer device to the interface unit after the reader/writer device is temporarily disconnected from the interface unit;
  - an unmount unit configured to set the memory card to an unmounted state;
  - a display unit configured to display information representing the disconnection between the interface unit and the reader/writer unit that is detected by the detection unit; and
  - a control unit configured to control the display unit, wherein the control unit controls, in response to the detection unit detecting that the reader/writer device is temporarily disconnected from the interface unit, the display unit not to display information about the temporary disconnection of the reader/writer device from the interface unit,
 wherein the temporary disconnection is a temporary electrical disconnection between the reader/writer device and the interface unit resulting from an event external to the interface unit and the reader/writer device, and wherein the event is noise in an electric signal between the interface unit and the reader/writer device that temporarily brings an electrical connection between the interface unit and the reader/writer device to an abnormal state during which the information processing apparatus cannot recognize the reader/writer device, and wherein the reader/writer device remains physically connected to the interface unit via a cable.
2. The information processing apparatus according to claim 1, further comprising a management unit configured to manage identification information for identifying the memory card inserted into the reader/writer device, wherein, in response to determining that the reader/writer device of which temporary disconnection is detected by the detection unit is a predetermined reader/writer device, the management unit manages the identification information such that the memory card, which is inserted into the reader/writer device that is reconnected to the interface unit after being temporarily disconnected from the interface unit, can be identified by the identification information assigned before the reader/writer device was temporarily disconnected from the interface unit.

## 11

3. The information processing apparatus according to claim 2, wherein the management unit manages information indicating whether the memory card inserted into the reader/writer device is in a mounted state or the unmounted state.

4. The information processing apparatus according to claim 1, wherein the reader/writer device comprises one or more slots for receiving one or more memory card.

5. The information processing apparatus according to claim 1, wherein the temporary disconnection is a temporary electrical disconnection between the reader/writer device and the interface unit resulting from an event external to the interface unit and the reader/writer device, wherein the event is not a result of a command from the information processing apparatus.

6. The information processing apparatus according to claim 5, wherein, in response to the reader/writer device being temporarily disconnected from the interface unit as a result of the event, a last device file name of the memory card before the reader/writer device was temporarily disconnected from the interface unit is stored.

7. The information processing apparatus according to claim 6, whereby a connection state after the temporary disconnection of the reader/writer device from the interface unit is not mismatched from a connection state before the temporary disconnection of the reader/writer device from the interface unit.

8. The information processing apparatus according to claim 1, wherein the control unit controls the display unit not to display information about the temporary disconnection of the reader/writer device from the interface unit whereby unnecessary confusion of a viewer of the display unit is avoided.

9. The information processing apparatus according to claim 1, wherein the temporary disconnection originates between the interface unit and the reader/writer device.

10. The information processing apparatus according to claim 9, wherein the temporary disconnection originating between the interface unit and the reader/writer device is a result of noise in an electric signal between the interface unit and the reader/writer device.

11. A method for controlling an information processing apparatus which includes an interface unit configured to connect a reader/writer device into which a memory card can be inserted and from which the memory card can be detached, a detection unit configured to detect, as detection result, a connection and then a disconnection between the interface unit and the reader/writer device, and a reconnection of the reader/writer device to the interface unit after the reader/writer device is temporarily disconnected from the interface unit, an unmount unit configured to set the memory card to an unmounted state, and a display unit, the method comprising: controlling the display unit to display information representing the disconnection between the interface unit and the reader/writer unit that is detected by the detection unit; and

## 12

controlling, in response to the detection unit detecting that the reader/writer device is temporarily disconnected from the interface unit, the display unit not to display information about the temporary disconnection of the reader/writer device from the interface unit,

wherein the temporary disconnection is a temporary electrical disconnection between the reader/writer device and the interface unit resulting from an event external to the interface unit and the reader/writer device, and

wherein the event is noise in an electric signal between the interface unit and the reader/writer device that temporarily brings an electrical connection between the interface unit and the reader/writer device to an abnormal state during which the information processing apparatus cannot recognize the reader/writer device, and wherein the reader/writer device remains physically connected to the interface unit via a cable.

12. A non-transitory computer-readable card storing a program that to cause an information processing apparatus to perform a method, wherein the information processing apparatus includes an interface unit configured to connect a reader/writer device into which a memory card can be inserted and from which the memory card can be detached, a detection unit configured to detect, as detection result, a connection and then a disconnection between the interface unit and the reader/writer device, and a reconnection of the reader/writer device to the interface unit after the reader/writer device is temporarily disconnected from the interface unit, an unmount unit configured to set the memory card to an unmounted state, and a display unit, the method comprising:

controlling the display unit to display information representing the disconnection between the interface unit and the reader/writer unit that is detected by the detection unit; and

controlling, in response to the detection unit detecting that the reader/writer device is temporarily disconnected from the interface unit, the display unit not to display information about the temporary disconnection of the reader/writer device from the interface unit,

wherein the temporary disconnection is a temporary electrical disconnection between the reader/writer device and the interface unit resulting from an event external to the interface unit and the reader/writer device, and

wherein the event is noise in an electric signal between the interface unit and the reader/writer device that temporarily brings an electrical connection between the interface unit and the reader/writer device to an abnormal state during which the information processing apparatus cannot recognize the reader/writer device, and wherein the reader/writer device remains physically connected to the interface unit via a cable.
